Abstract

We consider the problem of checking whether an implementation which contains parts with incomplete information is equivalent to a given full specification. We study implementations which are not completely specified, but contain boxes which are associated with incompletely specified functions (called Incompletely Specified Boxes or IS–Boxes).

After motivating the use of implementations with Incompletely Specified Boxes we define our notion of equivalence for this kind of implementations and present a method to solve the problem.

A series of experimental results demonstrates the effectiveness and feasibility of the methods presented.

1 Introduction

Verification, i.e. the check whether a circuit implementation fulfills its specification, is a crucial task in VLSI CAD. Growing interest in universities and industry has lead to new results and significant advances concerning topics like property checking, state space traversal and combinational equivalence checking [7, 10, 24, 19, 8, 26, 18].

For the purpose of this paper combinational equivalence checking is of particular interest. Here, the task is to check whether the Boolean functions corresponding to the specification and the implementation are the same. Besides functional validation by the application of test patterns, mainly two approaches are used to perform the equivalence check: One possibility is to translate implementation and specification into one Boolean formula which is satisfiable if and only if implementation and specification do not realize the same Boolean function [32, 22, 13]. As an alternative, implementation and specification can be transformed into a canonical form such that the equivalence check reduces to a check whether the canonical representations of implementation and specification are the same. BDDs [3] and Word-level Decision Diagrams such as *BMDs [6], HDDs [9] or K*BMDs [12] are popular choices for such canonical forms. Recent approaches integrate the use of BDDs and SAT–Solvers to combine advantages of both methods [15, 8, 26, 18]. When specification and implementation are structurally similar, correspondences between internal nodes can be used to simplify the verification problem [17, 27, 23, 19, 8, 26].

Recently, the problem of ‘Black Box Equivalence Checking’, which occurs when the specification is known, but only parts of the implementation are finished or known, has been addressed [16, 14, 29]. Parts of the implementation which are not finished or known are combined into ‘Black Boxes’. An error is found in an implementation with Black Boxes, if the implementation differs from the specification for all possible substitutions of the Black Boxes, i.e. there exists no completion of the partial implementation that makes it equivalent to the specification. There are several motivations for considering the Black Box Equivalence Checking problem: One application is equivalence checking in early stages of the design, when a partial implementation is not yet finished, a second application is the ‘abstraction from difficult parts’ in a (finished) implementation, and a third application consists
In error diagnosis, where candidate regions for design errors are combined into Black Boxes resulting in a Black Box Equivalence Checking problem.

In this paper we look into a related problem, which also handles implementations with incomplete information: Here we assume boxes, which are not completely unknown like Black Boxes, but rather implement an incompletely specified function. We call boxes of this kind Incompletely Specified Boxes or IS–Boxes. (For small examples of implementations with IS–Boxes see Figure 1. The IS–Box realizes the function $\frac{x_1}{1} + \frac{x_2}{1}$ with a don’t care for input vector $(0, 0)$. The corresponding specification for the whole circuit is the function $f = x_1 \oplus x_2$.)

Incompletely Specified Boxes can occur, when a larger design is partitioned into blocks, where some blocks are incompletely specified. After a partition of the design into (completely or incompletely specified) blocks has been done in an early stage of the design process, it should be checked, whether the partitioning result is still equivalent to the specification. (This includes — among other things — the question whether the don’t cares which were specified for IS–Boxes can really be used as don’t cares in this implementation containing IS–Boxes.) The current implementation is only correct, if it is equivalent to the specification for all possible assignments to the don’t cares of the IS–Boxes, since the designer of an IS–Box is allowed to assign the don’t cares arbitrarily and the implementation has to be correct independently from the actual choice for the don’t cares. An error is found, if there is an assignment to the don’t cares of the IS–Boxes, such that implementation and specification differ for at least one primary input vector. We believe that incorrect assumptions about the behaviour of the environment of subcircuits are frequent sources of design errors. For instance, the well–known bug in the Pentium floating point divider [30] was probably due to the incorrect assumption that certain inputs of the PD table to generate the quotient bits were don’t cares [5].

Another possible application of IS–Boxes could be the use of incompletely specified Intellectual Property cores (IP cores) in an implementation. Under the assumption that the IP vendor does not publish the don’t care assignment actually used in the design of the IP cores (for reasons of Intellectual Property protection), the IP cores have to be viewed as Incompletely Specified Boxes. The problem which has to be solved is to check whether specification and implementation with incompletely specified IP cores are equivalent. Again, specification and implementation with IS–Boxes can be called equivalent only if they are equivalent for all possible assignments to the don’t cares of the IS–Boxes (incompletely specified IP cores).

In this paper we present a method to solve the problem of equivalence checking for implementations with IS–Boxes. The problem is reduced to a symbolic, ROBDD based simulation [4] of the specification and a modified version of the implementation followed by a simple check for equality of ROBDDs.

Although we are using ROBDDs in our implementation of the method, it is straightforward how to apply the method also to equivalence checking based on Boolean satisfiability.

The paper is structured as follows: In Section 2 we give some preliminaries. The following section defines the problem of equivalence checking for implementations with Incompletely Specified Boxes, compares the notion of equivalence for implementations with IS–Boxes to the notion of equivalence for implementations with Black Boxes [16, 14, 29], and finally, it points out the relationship between our problem and the computation of satisfiability and observability don’t cares. In Section 4 we present our solution to the problem. Our method is evaluated by experiments in Section 5. The paper ends with some concluding remarks and directions for further research in Section 6.

2 Preliminaries

Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be a completely specified Boolean function with $n$ inputs.

Incompletely specified Boolean functions with domain $D$ are functions $f : D \rightarrow \{0, 1\}$ with $D \subseteq \{0, 1\}^n$. \{0, 1\}^n \ \text{\textbackslash} \ D$ is called ‘don’t care set’ of $f$. An incompletely specified function with domain $D$ can be represented by a pair (cover, dc) of (completely specified) Boolean functions, where dc is a characteristic function of the don’t care set, i.e., $dc : \{0, 1\}^n \rightarrow \{0, 1\}$ with $dc(\epsilon) = 1$ iff $\epsilon \notin D$ (\forall \epsilon \in \{0, 1\}^n), and cover : \{0, 1\}^n \rightarrow \{0, 1\}$ is an arbitrary function with the property $cover(\epsilon) = f(\epsilon)$ for all $\epsilon \in D$. A completely specified function $f' : \{0, 1\}^n \rightarrow \{0, 1\}$ is called a
Incompletely Specified Boxes

Implementations containing Incompletely Specified Boxes (or IS–Boxes) are circuits which contain boxes whose outputs are associated with incompletely specified functions. Let \( o_i \) be an output of an IS–Box \( IS_j \) with input variables \( i_1, \ldots, i_n \). Then \( o_i \) is associated with an incompletely specified function \( g_i \), which may be represented by a pair of completely specified functions \( (\text{cover}_i, \text{dc}_i) \), where \( \text{cover}_i \) and \( \text{dc}_i \) depend on variables \( i_1, \ldots, i_n \), and \( \text{dc}_i \) is the characteristic function of the don’t care set of \( g_i \).

Two small examples for implementations containing IS–Boxes are shown in Figure 1. The incompletely specified function \( g_1 \) associated with the IS–Box \( IS_1 \) in both examples is represented by \( (\text{cover}_1, \text{dc}_1) = (\overline{i_1} + \overline{i_2}, \overline{i_1} \cdot i_1) \), i.e., the don’t care set of \( g_1 \) is \( \{(0, 0)\} \). There are two possible completely specified extensions of \( g_1 \), namely the function \( g_1'(i_1, i_2) = \overline{i_1} + \overline{i_2} \) (where the don’t care \((0, 0)\) is set to 1) and the function \( g_1''(i_1, i_2) = i_1 \oplus i_2 \) (where the don’t care \((0, 0)\) is set to 0). The corresponding specification for the complete circuit is the function \( f^{SPEZ} = x_1 \oplus x_2 \).

3.1 Equivalence of specifications and implementations with IS–Boxes

When an IS–Box is used in a partition of a design into completely and incompletely specified boxes, implementation and specification can be called equivalent only if they represent the same Boolean function for all possible replacements of the incompletely specified functions by completely specified extensions, since the designer of an IS–Box has the freedom to choose an arbitrary assignment to the don’t cares and the overall circuit has to be correct in any case.

In the example of Figure 1 this means that the implementation is only correct, if it fulfills its specification both for the replacement of the IS–Box \( IS_1 \) by function \( g_1' \) and for the replacement of \( IS_1 \) by \( g_1'' \).

In the next section we present a method to decide, whether specifications and implementations containing IS–Boxes are equivalent in the sense defined above.
3.2 Comparison to equivalence for implementations with Black Boxes

Before presenting an algorithm for equivalence checking we look into the relationship between the equivalence checking problem for implementations with IS–Boxes and the equivalence checking problem for implementations with Black Boxes [16, 14, 29]. At first sight the equivalence checking problem for implementations with Black Boxes seems to be a special case of the corresponding problem for IS–Boxes, since Black Boxes are boxes of which we do not know anything, i.e., they can be modeled by incompletely specified functions where the domain is empty. However, the two problems are applied in different contexts which leads to different notions of equivalence:

- As already mentioned, an implementation with IS–Boxes is not correct, if there is a replacement of the IS–Boxes by completely specified extensions, such that the resulting implementation does not fulfill its specification.

- In contrast, an implementation with Black Boxes is not correct, if for all replacements of the Black Boxes by some completely specified functions the resulting implementation does not fulfill its specification. A Black Box represents a part of the implementation which is not yet finished. Thus, an error can only be reported, if the partial implementation can not be completed to a correct overall implementation by any implementation for the Black Boxes.

So we have two completely different notions of equivalence for Black Boxes and IS–Boxes.

3.3 Relation to the computation of satisfiability and observability don’t cares

The problem of equivalence checking for implementations with IS–Boxes is related to the computation of satisfiability and observability don’t cares [11] used in logic synthesis: In fact, we have to check, whether the don’t cares given for the IS–Boxes are satisfiability and observability don’t cares for the output functions of the boxes (under the assumption that the function of the overall circuit is defined by the specification). Thus, a naive approach to solve our problem — at least for the case that there is only one IS–Box with only one output — would be the computation of the complete set of all satisfiability and observability don’t cares for the IS–Box followed by a check, whether the given don’t care set for the IS–Box is a subset of the computed set. However, the following facts prohibit this approach:

- For large circuits, the computation of satisfiability and observability don’t cares can be expensive. For this reason, the computation of don’t cares for a subcircuit usually considers only an environment of the subcircuit and not the whole circuit leading to a subset of the don’t care set. However, we need the complete set of satisfiability and observability don’t cares to prove that the given don’t care set for an IS–Box is not correct.

- For IS–Boxes with several outputs and for several IS–Boxes in the implementation the situation will be much more complicated: In this case the flexibility has to be expressed by Boolean relations or by sets of Boolean relations, since the degree of freedom given at one output of an IS–Box depends upon the other outputs [33]. Also in this case we would need the complete information on flexibility for the IS–Boxes to decide whether the given don’t care sets for the IS–Boxes are not correct.

Fortunately, we do not need to compute the complete information on flexibility for the IS–Boxes to solve our problem. In the following section we present a much simpler solution to the equivalence checking problem for implementations with IS–Boxes.

4 Solution to equivalence checking for implementations with IS–Boxes

In this section we present a method to solve the equivalence checking problem for implementations containing IS–Boxes. Our approach is based on the following idea: We use additional variables
for the outputs of the IS–Boxes, which are used to model their function in the presence of don’t care values at the inputs of IS–Boxes. The complete behaviour of the implementation can then be represented by a function depending on the circuit’s primary input variables and the newly introduced variables. We obtain the following necessary and sufficient condition for equivalence: Specification and implementation are equivalent if and only if the resulting implementation function is exactly equal to the specification function. In particular, the implementation function finally must not depend on values assigned to the newly introduced variables.

We assume an implementation IMPL, which has \( n \) primary inputs \( x_1, \ldots, x_n \) and \( b \) IS–Boxes \( IS_1, \ldots, IS_b \). The IS–Boxes have \( l \) (\( l > b \)) outputs \( o_1, \ldots, o_l \).\(^1\) IS–Box \( IS_j \) depends on \( l_j \) input variables \( i_1^j, \ldots, i_{l_j}^j \). Each output \( o_i \) (\( 1 \leq i \leq l \)) of an IS–Box \( IS_j \) is associated with an incompletely specified function represented by the pair \( (\text{cover}_i, \text{dc}_i) \), where \( \text{dc}_i \) is the characteristic function of the don’t care set for \( o_i \). \( \text{cover}_i \) and \( \text{dc}_i \) depend on the input variables \( i_1^j, \ldots, i_{l_j}^j \) of IS–Box \( IS_j \).

Now we introduce new variables \( z_1, \ldots, z_l \) for the outputs \( o_1, \ldots, o_l \) of the IS–Boxes. For each output \( o_i \) of an IS–Box \( IS_j \) we define a function

\[
is_i(i_1^j, \ldots, i_{l_j}^j, z_i) = \overline{\text{dc}_i} \cdot \text{cover}_i + \text{dc}_i \cdot z_i
\]

depending on input variables \( i_1^j, \ldots, i_{l_j}^j, z_i \).

Let \( \text{IMPL}_{\text{cs}} \) be the circuit which results from the implementation with IS–Boxes by replacing the outputs of IS–Boxes by functions \( is_i \), i.e., by replacing output \( o_i \) of IS–Box \( IS_j \) by function \( is_i(i_1^j, \ldots, i_{l_j}^j, z_i) \), respectively. Moreover, let \( f_k^{\text{IMPL}_{\text{cs}}}(x_1, \ldots, x_n, z_1, \ldots, z_l) \) be the Boolean function computed by output \( k \) of \( \text{IMPL}_{\text{cs}} \) and let \( f_k^{\text{SPEZ}} \) be the corresponding output of the specification \( \text{SPEZ} \).

Then the following theorem gives a necessary and sufficient condition for the correctness of the implementation with IS–Boxes:

**Theorem 4.1** Using the notations defined above the following two propositions are equivalent:

1. Output \( k \) of implementation \( \text{IMPL} \) is not equivalent to output \( k \) of specification \( \text{SPEZ} \), i.e., there is a replacement of the outputs \( o_i \) of IS–Boxes \( IS_j \) by completely specified extensions \( cs_i(i_1^j, \ldots, i_{l_j}^j) \) leading to a circuit \( \text{IMPL}_{\text{cs}} \), such that \( f_k^{\text{IMPL}_{\text{cs}}}(x_1, \ldots, x_n) \neq f_k^{\text{SPEZ}}(x_1, \ldots, x_n) \).

2. \( f_k^{\text{IMPL}_{\text{cs}}} \neq f_k^{\text{SPEZ}} \), i.e., there is \( (\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l) \in \{0, 1\}^{n+l} \) with \( f_k^{\text{IMPL}_{\text{cs}}} (\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l) \neq f_k^{\text{SPEZ}} (\epsilon_1, \ldots, \epsilon_n) \).

**Proof:**

‘2. \( \Rightarrow 1. \):

Let \( (\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l) \in \{0, 1\}^{n+l} \) be an input vector which distinguishes between \( f_k^{\text{IMPL}_{\text{cs}}} \) and \( f_k^{\text{SPEZ}} \), i.e., \( f_k^{\text{IMPL}_{\text{cs}}} (\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l) \neq f_k^{\text{SPEZ}} (\epsilon_1, \ldots, \epsilon_n) \).

Then we define \( \text{IMPL}_{\text{cs}} \) as follows: For each output \( o_i \) of an IS–Box \( IS_j \) we choose

\[
\text{cs}_i(i_1^j, \ldots, i_{l_j}^j) = \overline{\text{dc}_i} \cdot \text{cover}_i + \text{dc}_i \cdot \delta_i,
\]

i.e., all don’t cares of output \( o_i \) of IS–Box \( IS_j \) are fixed to \( \delta_i \). Under the assumption that input vector \( (\epsilon_1, \ldots, \epsilon_n) \) is applied to circuit \( \text{IMPL}_{\text{cs}} \) and input vector \( (\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l) \) is applied to circuit \( \text{IMPL}_{\text{cs}} \), we can prove that all corresponding signals in \( \text{IMPL}_{\text{cs}} \) and \( \text{IMPL}_{\text{cs}} \) have the same value. The proof is done by induction on the depth of the signals:

Signals with depth 0 are primary inputs. Corresponding primary inputs \( x_i \) of \( \text{IMPL}_{\text{cs}} \) and \( \text{IMPL}_{\text{cs}} \) have values \( \epsilon_i \). Now consider corresponding signals with depth \( d > 0 \):\(^2\)

---

\(^1\) Each IS–Box has at least one output.

\(^2\) Since both \( \text{IMPL}_{\text{cs}} \) and \( \text{IMPL}_{\text{cs}} \) result from \( \text{IMPL} \) by replacement of IS–Boxes, ‘corresponding signals’ are signals which result from identical signals in \( \text{IMPL} \).
Case 1: The signals are computed by a gate $g$ (not by an IS–Box).

The input signals of $g$ for $\text{IMPL}_c$s and $\text{IMPL}_z$ are corresponding signals and have the same value according to the induction hypothesis. Thus the signals computed by $g$ in $\text{IMPL}_c$s and $\text{IMPL}_z$ are the same.

Case 2: The signals are computed by output $o_i$ of an IS–Box $IS_j$.

Let the input signals of $IS_j$ be $i_1^j, \ldots, i_{l_j}^j$, $i_1^j, \ldots, i_{l_j}^j$ are corresponding signals in $\text{IMPL}_c$s and $\text{IMPL}_z$ and have the same values (according to the induction hypothesis). Let the vector of values for $i_1^j, \ldots, i_{l_j}^j$ be $(\alpha_1, \ldots, \alpha_{l_j})$. In $\text{IMPL}_z$, $o_i$ is associated with a function $i_s(i_1^j, \ldots, i_{l_j}^j, z_i) = \overline{dc_i} \cdot \text{cover}_i + dc_i \cdot z_i$. In $\text{IMPL}_c$, $o_i$ is associated with function $c_s(i_1^j, \ldots, i_{l_j}^j) = \overline{dc_i} \cdot \text{cover}_i + dc_i \cdot \delta_i$.

If $dc_i(\alpha_1, \ldots, \alpha_{l_j}) = 0$, then both $i_s$ and $c_s$ compute $\text{cover}_i(\alpha_1, \ldots, \alpha_{l_j})$; if $dc_i(\alpha_1, \ldots, \alpha_{l_j}) = 1$, both $i_s$ and $c_s$ compute value $\delta_i$, since $z_i$ is a primary input of $\text{IMPL}_z$ and is set to $\delta_i$.

Since all corresponding signals in $\text{IMPL}_c$s and $\text{IMPL}_z$ have the same value, we can conclude that $f_k^{\text{IMPL}_c}(\epsilon_1, \ldots, \epsilon_n) = f_k^{\text{IMPL}_z}(\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l)$ and thus $f_k^{\text{IMPL}_c}(\epsilon_1, \ldots, \epsilon_n) \neq f_k^{\text{IMPL}_z}(\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l)$.

\[1. \Rightarrow 2:\]

Assume that there is a replacement of the outputs $o_i$ of IS–Boxes $IS_j$ by completely specified extensions $c_s(i_1^j, \ldots, i_{l_j}^j)$, such that $f_k^{\text{IMPL}_c}(\epsilon_1, \ldots, \epsilon_n) \neq f_k^{\text{IMPL}_z}(\epsilon_1, \ldots, \epsilon_n)$ for $(\epsilon_1, \ldots, \epsilon_n) \in \{0, 1\}^n$.

The outputs $o_i$ of IS–Boxes $IS_j$ are associated with incompletely specified functions represented by $(\text{cover}_i, dc_i)$ ($1 \leq i \leq l$). Since $c_s$ is a completely specified extension of the incompletely specified function represented by $(\text{cover}_i, dc_i)$, we have $c_s = \overline{dc_i} \cdot \text{cover}_i + dc_i \cdot h_i$ for some Boolean function $h_i$ depending on variables $i_1^j, \ldots, i_{l_j}^j$.

For primary input vector $(\epsilon_1, \ldots, \epsilon_n)$ let $\delta_i$ be the values computed by outputs $o_i$ of IS–Boxes $IS_j$ in circuit $\text{IMPL}_c$s ($1 \leq i \leq l$). Now we claim that $f_k^{\text{IMPL}_c}(\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l) = f_k^{\text{IMPL}_z}(\epsilon_1, \ldots, \epsilon_n)$.

As in part ‘2. $\Rightarrow 1.$’, we prove by induction on the depth of signals that input vectors $(\epsilon_1, \ldots, \epsilon_n)$ and $(\epsilon_1, \ldots, \epsilon_n, \delta_1, \ldots, \delta_l)$ lead to the same values for corresponding signals in $\text{IMPL}_c$s and $\text{IMPL}_z$. It is easy to see that this is true for signals with depth 0 and for signals which are computed by gates different from outputs of IS–Boxes. Now consider a signal which is computed by output $o_i$ of an IS–Box $IS_j$. Let $(\alpha_1, \ldots, \alpha_{l_j})$ be the vector of values for the input signals $i_1^j, \ldots, i_{l_j}^j$ of $IS_j$ in $\text{IMPL}_c$s and $\text{IMPL}_z$. If $dc_i(\alpha_1, \ldots, \alpha_{l_j}) = 0$, then both $i_s$ in $\text{IMPL}_z$ and $c_s$ in $\text{IMPL}_c$s compute $\text{cover}_i(\alpha_1, \ldots, \alpha_{l_j})$. If $dc_i(\alpha_1, \ldots, \alpha_{l_j}) = 1$, then $c_s$ computes $h_i(\alpha_1, \ldots, \alpha_{l_j}) = \delta_i$ and $i_s(i_1^j, \ldots, i_{l_j}^j, z_i) = \overline{dc_i} \cdot \text{cover}_i + dc_i \cdot z_i$ computes $\delta_i$, too, since $z_i$ is set to $\delta_i$ by the assignment made to the primary inputs of $\text{IMPL}_z$.

\[\square\]

Based on Theorem 4.1 we use the following method to check equivalence of specifications and implementation containing IS–Boxes:

1. Replace each output $o_i$ of an IS–Box $IS_j$, which is associated with an incompletely specified function represented by $(\text{cover}_i, dc_i)$, by the function $i_s = \overline{dc_i} \cdot \text{cover}_i + dc_i \cdot z_i$ with a new variable $z_i$.

2. Compute for each output $k$ of the resulting circuit $\text{IMPL}_z$ the BDD for $f_k^{\text{IMPL}_z}$ by symbolic simulation.

3. Compute for each output $k$ of the specification the BDD for $f_k^{\text{IMPL}_c}$ by symbolic simulation.
4. Check whether the BDDs for \( f^\text{IMPL}_k \) and \( f^\text{SPEZ}_k \) are different for some primary output \( k \). If this is the case, then specification and implementation are not equivalent, otherwise they are equivalent.

**Example 4.1** Consider the implementations in Figure 1. Both implementations contain one IS–Box realizing an incompletely specified function represented by \((\text{cover}_1, \text{dc}_1) = ((i_1^1 + i_2^1, i_1^2 \cdot i_2^2))\). The corresponding specification is the function \( f^\text{SPEZ} = x_1 \oplus x_2 \).

For symbolic simulation, the IS–Box is replaced by \( i_1^1 = \text{dc}_1 \cdot \text{cover}_1 + \text{dc}_1 \cdot z_1 = (i_1^1 + i_2^2)(i_1^1 + i_2) + i_1^1 i_2 z_1 \). For each gate, symbolic simulation computes the function realized by the gate depending on primary inputs. Gates are processed in topological order.

For Implementation 1, symbolic simulation computes

- for \( o_1 \): \( f^\text{IMPL}_{o_1} = (x_1 + x_2)(\overline{x_1} + \overline{x_2}) + \overline{x_1} x_2 z_1 = x_1 \overline{x_2} + \overline{x_1} x_2 + \overline{x_1} x_2 z_1 \),
- for \( l \): \( f^\text{IMPL}_{l} = x_1 \cdot f^\text{IMPL}_{o_1} = x_1 \cdot \overline{x_2} \),
- for \( r \): \( f^\text{IMPL}_{r} = x_2 \cdot f^\text{IMPL}_{o_1} = \overline{x_1} \cdot x_2 \),

and finally \( f^\text{IMPL} = f^\text{IMPL}_{l} + f^\text{IMPL}_{r} = x_1 \cdot \overline{x_2} + \overline{x_1} \cdot x_2 = x_1 \oplus x_2 \).

Since \( f^\text{IMPL} = f^\text{SPEZ} \), the implementation is equal to the specification independently from the assignment to the don’t cares of the IS–Box and thus implementation and specification are equivalent.

For Implementation 2, symbolic simulation computes

- for \( o_1 \): \( g^\text{IMPL}_{o_1} = (x_1 + x_2)(\overline{x_1} + \overline{x_2}) + \overline{x_1} x_2 z_1 = x_1 \overline{x_2} + \overline{x_1} x_2 + \overline{x_1} x_2 z_1 \),
- for \( l \): \( g^\text{IMPL}_{l} = x_1 \cdot g^\text{IMPL}_{o_1} = x_1 \cdot \overline{x_2} \),
- for \( r \): \( g^\text{IMPL}_{r} = x_2 \cdot g^\text{IMPL}_{o_1} = \overline{x_1} \cdot x_2 \),

and finally \( g^\text{IMPL} = g^\text{IMPL}_{l} + g^\text{IMPL}_{r} = x_1 \cdot \overline{x_2} + \overline{x_1} x_2 z_1 + \overline{x_1} \cdot x_2 \).

Since \( g^\text{IMPL} \neq f^\text{SPEZ} = x_1 \oplus x_2 \), implementation and specification are not equivalent. Note that in this example there is a don’t care assignment for the IS–Box, such that implementation and specification will become equal. If the output of the IS–Box for input \((0, 0)\) is chosen to be 0, then implementation and specification will be equal. However, if the output of the IS–Box for input \((0, 0)\) is 1, then implementation and specification will not be equal and thus, the specification and the implementation containing an IS–Box are called not equivalent, since the implementation has to fulfill its specification for all possible assignments to the don’t cares.

## 5 Experimental results

To evaluate our method for equivalence checking in the presence of IS–Boxes we implemented the described procedure using CUDD 2.3.0 [31] as the underlying BDD package. Dynamic reordering [28] was activated during all experiments. The experiments were performed on a Pentium III PC with 550 MHz, 1 GB memory, running Linux 6.3.

Although, for the purpose of this paper, our implementation is restricted to BDDs, it should be mentioned that it is straightforward to incorporate other approaches like SAT based equivalence checking [32, 22, 13] or approaches combining the strengths of BDD based and SAT based methods by a tight integration [15, 8, 26, 18]. Furthermore, for specifications and implementations having structural similarities, methods which identify equivalences between internal nodes to simplify the verification problem [19, 8, 26] are applicable to our problem, too.

To obtain circuits with IS–Boxes we generated implementations with IS–Boxes from benchmark circuits: For each benchmark circuit a certain fraction of the gates was randomly selected to form IS–Boxes. In a first experiment (Table 1) we included 10% of the gates in one IS–Box, in a second
Tables 1, 2 and 3 show the results of the experiments. In columns 1, 2, and 3 the names of the benchmarks, and the numbers of inputs and outputs are given. Column 4 gives the numbers of ROBDD nodes needed to represent the specification; column 5 shows the CPU times in seconds to compute the BDD representation of the specification. Column 6 gives the average fraction of minterms, which are used as don’t cares for the different outputs of the IS–Boxes. Then the results for two sets of experiments are presented: For the first experiment, where no errors were inserted, columns 7 and 8 show the numbers of BDD nodes and the CPU times needed for symbolic simulation of the implementation and in columns 9 and 10 the same information is given for the second experiment using error insertions.

The observations made based on the experiments are the same for Tables 1, 2 and 3 (10% of the gates included in one IS–Box, 10% of the gates included in five IS–Boxes and 40% of the gates included in one IS–Box): The symbolic simulation of implementations with IS–Boxes shows no performance degradation at all compared with the symbolic simulation of the specification. This observation is true for different sizes and numbers of IS–Boxes. In our experiments this property also did not change when errors were inserted into the implementations with IS–Boxes. This clearly demonstrates the feasibility of our approach.

Table 1: 10% of the gates included in one IS–Box experiment (Table 2) 10% of the gates in five IS–Boxes and in a third experiment (Table 3) 40% of the gates in one IS–Box. The incompletely specified functions for the outputs of the IS–Boxes were computed based on the original benchmark circuit: For an output of an IS–Box the incompletely specified function is represented by a pair \((cover_i, dce_i)\). The function \(cover_i\) was chosen as the function originally implemented in the benchmark circuit and the function \(dce_i\) was obtained by computing satisfiability and observability don’t cares [11] for the IS–Box. Both \(cover_i\) and \(dce_i\) were represented by a BDD and were associated with the IS–Box.

The original benchmark circuit was used as the specification.

In a first set of experiments we used the circuit with IS–Boxes computed as described above as the implementation. In this case, specification and implementation are equivalent, since the don’t cares for the outputs of the IS–Boxes are satisfiability or observability don’t cares of the Boxes in the original benchmark circuit. In a second set of experiments we inserted errors into the implementations with IS–Boxes to check the robustness of our method for erroneous implementations. We randomly selected a gate, which did not belong to an IS–Box, and inserted an error. The error type was also selected randomly between several choices: We added/removed an inverter for an input or output signal of the gate, changed the type of the gate \((CP/D2/BE \rightarrow D3/D6/BE\) or \(D3/D6/BE \rightarrow CP/D2/BE\)) or removed an input line from an \(CP/D2/BE\) or \(D3/D6\) gate.

All reported results are an average on 5 different random selections of IS–Boxes and in the case of error insertions also an average on 100 different random selections of error insertions.\(^3\)

\(^3\)Of course, the circuit modifications described above do not necessarily lead to errors in the implementation. For our results we used only those modifications, which really lead to errors.

6 Conclusion and future work

In this paper we introduced the concept of equivalence checking for implementations with IS–Boxes. The relationship of this notion of equivalence to the equivalence for implementations containing Black Boxes was clarified. We presented a method based on symbolic simulation to solve the problem of equivalence checking for implementations with IS–Boxes. Experimental results prove the feasibility of the approach.

It is straightforward that the method of Section 4 can also be used in connection with equivalence checking based on Boolean satisfiability. The transformation of the problem into a CNF formula can be done using methods from [20, 22], e.g.. Since after the transformation of Section 4 the remaining task consists in comparing two combinational circuits, an incorporation of recently presented methods combining the strengths of BDD based and SAT based algorithms by a tight integration can be applied to our approach, too. For the same reason also methods to identify equivalences between internal nodes to simplify the verification problem for circuits with structural similarities are applicable to our method.

For the future, we are planning to generalize the approach to the verification of sequential circuits containing IS–Boxes.
